## PREFACE

Professor Visser's new analysis of the two fundamental solar cycles, the cycle of the sun's activity and the cycle of the sun's rotation, as shown by sunspot numbers and some terrestrial phenomena, is an attempt to deduce some essential features of these cycles by means of a method of analysis specially adapted to this purpose.

The application of binomial averages of sunspot numbers through five successive solar rotations to the whole series of data running from 1863 to 1959 does mean an extremely time-consuming calculation which was undertaken by the author himself. A number of tables in appendix contains the results of the enumerations. Although indispensable, these tables are perhaps less instructive than the series of figures representing in detail the course of the nine solar cycles which have elapsed since 1863.

Moreover suggestive light is thrown on the fluctuations in geomagnetic, ionospheric and meteorological elements.

It is my hope that the present investigation and refinements of earlier analyses may contribute to the physical interpretation of some solar phenomena and some important solar-terrestrial relationships.

The Director in Chief
Royal Netherlands Meteorological Institute
Ir. C. J. Warners

## 1. GENERAL REMARKS

### 1.1 The character of the 27-day solar rotation period

The daily relative sunspot numbers as collected and published by the "Eidgenössische Sternwarte" at Zürich, are known over a great number of years. Zürich gives also monthly and annual averages of these daily numbers and moreover smoothed monthly values. Monthly and annual average sunspot numbers, however, have no heliophysical meaning because the month and the year are not relevant to the Sun's activity. The only acceptable average is that based upon the Sun's synodic rotation. A duration of 27,2753 days has been used in the Nautical Almanac. This figure is not as accurate as is suggested by the four decimal places, claiming an exactitude of 3,4 seconds. The Sun's rotation is variable depending on the heliographic latitude, and its synodic rotation changes in the course of a year in accordance with Kepler's second law. At high solar latitudes ( $35-40^{\circ}$ ) where sunspot activity starts anew at each minimum of the 11 -year cycle, the duration is 27,75 days, at low solar latitudes, where the sunspots die out towards the end of the 11 -year cycle, it is only 27,05 days. The average duration mentioned above is valid for a latitude of about $15^{\circ}$. The duration when the earth is in its perihelium (January) is 27,34 days, when the earth is in its aphelium (July) 27,20 days. These variations of the duration, even present in the first decimal place, show the unreliability of the 4 decimal places given. Yet I have adopted 27,275 days for the Sun's rotational period in order to link my results with the average duration generally accepted.

Actually the Sun's rotation is the cause of the appearance of an approximate 27 -day periodicity in a number of solar and terrestrial phenomena. This 27-day periodicity, however, is highly capricious: it starts at some arbitrary moment, it dies out at another moment and it may be absent during long time intervals. When average values of its wave length and amplitude are calculated over many years the period fades out or is only poorly revealed.

As an example of the application of this unsatisfactory method Buys Ballot's investigation may be recalled here. The present author gave a short account of it in the Centenary Memorial Book 1854-1954 of the Royal Netherlands Meteorological Institute, in the following words.

Buys Ballot occupied himself from 1846 to 1886 with the investigation of a temperature period of about 27 days. He arranged the daily temperatures observed at Zwanenburg from 1729-1861, and later at Utrecht, in 28 columns. When a sinusoidal 28 -day period exists with a maximum in the first half and a minimum in the second half of the period the temperature differences between the days 1 and 15 , 2 and 16 etc. must be positive. Buys Ballot arranged the differences

Fig. 1. Buys Ballot's period, 1729-1884.
in 14 columns and mentioned all positive differences "profit", all negative ones "loss". This profit and loss account gave a surplus of $26665^{\circ} \mathrm{F}$ in 145 years. This impressive amount, however, shows a greatest difference of only $0,5^{\circ} \mathrm{F}$ per period, being the amplitude of the temperature wave. By applying corrections Buys Ballot deduced in 1876 a duration of the period of 27,682 days. In his last publication (1886), concerning 2046 periods, he modified the duration to 27,675 days. His "Tableau récapitulatif" has been graphically reproduced in Fig. 1. The amount of profit in his tables is notably large. Some reality may be ascribed to this period, the practical value, however, is negligible. Today it is well known that solar activity influences atmospheric temperatures. Therefore Buys Ballot's temperature wave may be due to the Sun's rotation, but possibly the duration has been distorted by his method of working. A closer analysis of the data is required to disclose the cause of the discrepancy in his results.
A report of such a closer analysis is now given in chapter 5.

### 1.2 The enumeration of the solar rotations

There are two methods of enumerating the solar rotations.
$1^{\circ}$ The enumeration is based strictly on the Sun's synodic rotation (Carrington). In the Greenwich Photoheliographic Results it is used as follows: The commencement of each is defined by the coincidence of the assumed prime meridian with the central meridian, the assumed prime meridian being that meridian which passed through the ascending node of the Sun's equator on the ecliptic at mean noon of 1854, January 1, the assumed period of the Sun's sidereal rotation being 25,38 days. This definition has always been used in the Nautical Almanac (Greenwich, 1955). This enumeration reached No. 1396 in 1958, January 12,96 (U.T.).
$2^{\circ}$ The enumeration is based on a constant period of exactly 27 days (J. Bartels). Bartels speaks of the "geophysical rotation time" and may do so because as a rule the solar influence on geophysical phenomena is limited to sequences of only a few periods, the small discrepancies allowed being immaterial. Yet, as I have pointed out earlier, during long sequences the differences become obvious. Bartels's enumeration started February 8, 1832. Rotation No. 1705 has been reached January 26, 1958.

### 1.3 The new analysis

The present investigation is concerned with solar observations made since January 1, 1863. Before this date Wolf published in his "Mitteilungen über Sonnenflecken" daily values of $g$ (number of groups) and $f$ (number of spots). He has added monthly averages of relative sunspot numbers, but it is not quite clear how he deduced these early averages. Therefore I have omitted the observations made in the years before 1863. From the above date onwards the "Mitteilungen" contain the daily relative sunspot numbers. Up to January 1872 the monthly means differ from those published by Waldmeier [1957, p. 143; cited in this paper as E. und P.]. Yet I have preferred Wolf's daily figures for the years 1863-1871 inclusive. The number of missing days in these years amounts to an annual average of 13 . They have been filled up by linear interpolation.

For the whole interval 1863-1958 running 27-day averages have been calculated. In order to deduce the average rotation period of 27,275 days, I have proceeded as follows. The duration of 100 periods of 27,27 days equals that of 101 periods of 27 days. Therefore I have omitted systematically one day in each 3 or 427 -day periods in such an order that one period is eliminated in 101 periods. So we get a close approximation of a period of 27,27 days. The third decimal 5 is accounted for by deleting one day for each 20027 -day periods. As to the fourth decimal 3 (Nautical Almanac), in 1000 periods the difference amounts to 0,3 day. Since nowadays only 1400 periods have expired it is evident that the fourth decimal may be wholly neglected.

As the basis of this reduction the first day of Rotation No. 1369, January 7, 1956 (beginning January 7,51), has been taken. Comparison with the rotation numbers of Greenwich Observatory (1874-1954) showed that the difference with the true data never exceeded 1,5 days, this being immaterial for the present purpose.

In this way a series of running daily averages in which the rotation period is eliminated, has been obtained, representing the slow variations of solar activity (e.g. the 11 -year cycle). The differences between the 27,275-day averages on one day and the sunspot numbers observed on the same day, give the rotation period, when present, by more or less regular sequences of positive and negative deviations.

This method has great advantages. The results are freed from the terrestrial units of months and years and they represent both the slow variations and the rotation period when present.

The same procedure has been applied to the daily maximum temperatures at Utrecht-De Bilt (since 1863), the magnetic character figures $C$ (since 1891) and $K$ (since 1940) both for De Bilt-Witteveen, and the ionospheric index $I$, determined at De Bilt since 1952 (daily sums of 8 three-hour intervals). These data will now be treated only briefly, but will be fully discussed in a following communication.

### 1.4 The smoothing of the relative sunspot numbers

Waldmeier [E. und P., p. 140] has applied a smoothing method which he describes as follows.
"Die ausgeglichenen Relativzahlen werden bestimmt, indem man je 12 aufeinanderfolgende Monatsmittel der beobachteten Relativzahlen zum Mittel zusammenfasst und aus je zwei solchen aufeinanderfolgenden Zahlen noch einmal das Mittel nimmt. Diese ist die ausgeglichene Relativzahl für die Mitte des mittleren der so vereinigten 13 Monate. Durch diese Ausgleichung werden die kurzperiodischen Schwankungen eliminiert und die langperiodischen treten deutlicher hervor. Tabelle 32 enthält die vollständige Reihe der ausgeglichenen Monatsmittel. Das in den Tabellen 31 und 32 enthaltene Material bildet den Grundstock, auf den sich fast alle die zahlreichen statistischen Untersuchungen über die Variationen der Fleckentätigkeit sowie über die solar-terrestrischen Zusammenhänge ausbauen."
This method has not been changed since Wolf in 1862 devised it. An uninterrupted homogeneous series of sunspot data has been obtained in this manner, but the smoothing method is not in essence statistically justified. It must be considered as an arbitrary step in the direction of characterizing sunspot activity. As a matter of fact strongly smoothed figures are arrived at, from which the short periods are eliminated. When we wish to investigate these short periods, then a more satisfying smoothing process is needed. Moreover it will be shown that Wolf-Waldmeier's procedure gives to a certain extent a wrong picture of the course which the sunspot phenomenon takes.

In the present investigation I started with the smoothing method ( $R_{1}+$ $+2 R_{2}+R_{3}$ ): $2^{2}$. In this way a new row of figures is obtained and hereupon the same procedure may be applied. The result is represented by the formula

$$
\left(R_{1}+3 R_{2}+3 R_{3}+R_{4}\right): 2^{3} .
$$

Proceeding in the same way, we obtain

$$
\begin{aligned}
& \left(R_{1}+4 R_{2}+6 R_{3}+4 R_{4}+R_{5}\right): 2^{4} \\
& \left(R_{1}+5 R_{2}+10 R_{3}+10 R_{4}+5 R_{5}+R_{6}\right): 2^{5} \\
& \text { and so on. }
\end{aligned}
$$

Yet, after a few steps the "amelioration" becomes negligible. It appeared to be unnecessary to go beyond the 5 original data and the divisor $2^{4}$ (see also 2.3).

The coefficients of the formulae are the binomial coefficients and the averages are obtained by successive powers of 2 . These averages will be called "binomial averages of the $n$th power" and denoted by $R b n, n$ being the exponent of 2 . They are calculated with the aid of ( $n+1$ ) original data. So I have calculated the binomial averages of the 4th power, involving 5 data, Rb4.

The advantages of this smoothing method are

1. the time interval, 5 synodic solar rotation periods (about 4,5 months), is much shorter than the 13 months used in the Zürich method;
2. the central data receive more weight than the extreme ones, whereas the Zürich Observatory gives the same weight to all of them, with the exception of the two outermost ones which receive the weight $\frac{1}{2}$.
So the short periods stand out clearly and a much more satisfying insight into the features of sunspot activity is obtained.

### 1.5 The results

Table 1 (Appendix), containing the results, has been composed as follows. Since two years ( 730 days) have the same duration as 27 periods of 27 days ( 729 days), 27 periods have been distributed over two years in such a way that as a rule years with 13 and 14 periods alternate. The periods are inscribed so that the first day of the first period in each year falls in January, the last day of the last one in December. In this manner the 12 months are distributed regularly over the columns of the table.

Column 1 contains the years, from 1863 up to the beginning of 1959, column 2 the numbers of the 11-year sunspot cycles, $10-19$, and the Carrington numbers referring to the dates in January in the next column. Then follow 27 columns with the data $R_{m}$, being the averages of the 27,275 -day period, and $R b 4$, the smoothed averages calculated with the aid of the procedure $b 4$, elucidated above. Predominant peaks have been printed in bold type, the maxima of the 11 -year cycles are moreover underlined. The minima of these cycles have been printed in italics.

## 2. THE BEHAVIOUR OF THE 11-YEAR CYCLE

### 2.1 The epochs of the maxima and the minima

The epochs of the smoothed maxima and minima ( $R b 4$ ) of the 11-year sunspot cycles, compared with those of Wolf-Waldmeier, have been gathered in Table 2.

Table 2. Maxima and Minima of the 11-year solar cycle

| No. | $R b 4$ - averages |  |  |  |  |  | Waldmeier |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | minimum |  |  | maximum |  |  | minimum |  | maximum |  |
|  | Carr. | year | min | Carr. | year | max | year | min | year | max. |
| 11 | 178 | 1867,1 | 2,4 | 221 | 1870,3 | 163,0 | 1867,2 | 5,2 | 1870,6 | 140,5 |
| 12 | 338 | 1879,0 | 0,6 | 406 | 1884,1 | 89,4 | 1878,9 | 2,2 | 1883,9 | 74,6 |
| 13 | 483 | 1889,9 | 1,7 | 533 | 1893,6 | 101,0 | 1889,6 | 5,0 | 1894,1 | 87,9 |
| 14 | 641 | 1901,7 | 1,4 | 714 | 1907,1 | 84,2 | 1901,7 | 2,6 | 1907,0 | 64,2 |
| 15 | 798 | 1913,4 | 0,2 | 855 | 1917,6 | 136,3 | 1913,6 | 1,5 | 1917,6 | 105,4 |
| 16 | 941 | 1924,1 | 2,1 | 997 | 1928,2 | 88,4 | 1923,6 | 5,6 | 1928,4 | 78,1 |
| 17 | 1073 | 1933,9 | 1,3 | 1121 | 1937,5 | 138,6 | 1933,8 | 4,3 | 1937,4 | 119,2 |
| 18 | 1213 | 1944,4 | 2,8 | 1256 | 1947,6 | 181,2 | 1944,2 | 7,7 | 1947,5 | 151,8 |
| 19 | 1342 | 1954,0 | 1,4 | 1393 | 1957,8 | 237,4 | 1954,3 | 3,4 | 1957,8 | 199,0 |

Furthermore some notable differences between Waldmeier's summarizing table 33 (E. und P., p. 153) and the smoothed amounts given by table 32 (p. 148-150) are assembled in Table 3.

Table 3. Notable differences between Waldmeier's two tables of sunspot maxima and minima

|  | table 33 |  | table 32 |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| minimum | 1889,6 | 5,0 | 1890, Feb | 5,0 | $\begin{aligned} & \text { 1889, Jun 6,3; Jul 6,5; } \\ & \text { Aug 6,3 } \end{aligned}$ |
| minimum | 1901,7 | 2,6 | 1902, Jan | 2,6 | 1901, May 2,8; Jun 2,8; <br> Jul 3,0; Aug 3,1 |
| maximum | 1907,0 | 64,2 | 1906, Feb | 64,2 | $\begin{aligned} & \text { 1906, Dec } 60,1 ; 1907 \text {, Jan } 56,9 \\ & \text { Feb } 55,0 \end{aligned}$ |
| maximum | 1947,5 | 151,8 | $\begin{aligned} & \text { 1947, May } \\ & \text { 1948, Oct } \end{aligned}$ | $\begin{aligned} & 151,8 \\ & 148,5 \end{aligned}$ |  |

As regards 1906 Baur (1951) has considered 1906,4 to be the epoch of the minimum.

Since Waldmeier does not refer in table 32 to the epochs of table 33 (see righthand part of Table 3) I have considered the epochs of Waldmeier's table 32 to represent the true extremes, which means the assumption of sunspot minima in 1890,2 and 1902,1, and of maxima in 1906,2 and 1947,5. Notable differences between Waldmeier's extremes and those according to the $b 4$ -
procedure (see Table 2) are: cycle 11, maximum 1870,6 and 1870,3; cycle 13, minimum 1890,2 and 1889,9 ; maximum 1894,1 and 1893,6 ; cycle 14 , minimum 1902,1 and 1901,7; maximum 1906,2 and 1907,1; cycle 16, minimum 1923,6 and 1924,1; cycle 19, minimum 1954,3 and 1954,0.

### 2.2 Waldmeier's three groups of solar cycles

Waldmeier [1935] has subdivided the 18 eleven-year cycles since 1750 into three groups, characterized by different lengths of the ascending branch of the corresponding sunspot curves.

Table 4. Waldmeier's three groups of sunspot cycles

|  | mean max <br> sunspot <br> number <br> smoothed | ascending branch   <br>    <br>    <br> mean duration   <br> min - max   | limiting <br> durations | cycle No. |
| :--- | :---: | :---: | :---: | :---: |
| A. 6 strong cycles | 145,1 | 3,5 years | $2,9-4,6$ years | 3 and 9 |
| B. 6 moderate cycles | 102,1 | 4,3 | $3,2-6,3$ | 2 and 1 |
| C. 6 weak cycles | 64,4 | 5,7 | $4,8-6,9$ | 16 and 5 |

Cycle numbers. A. 3, 18, 8, 4, 11, 9;
B. $17,2,15,10,13,1$;
C. $16,12,7,14,5,6$.

The limiting durations of the ascending branch for each group show that group B is wholly overlapped by the groups A and C. It may better be deleted, by which the following arrangement results,

| 9 strong cycles | 134,5 | 3,5 years | $2,9-4,6$ |
| :--- | ---: | :--- | ---: |
| 9 weak cycles | 73,2 | 5,5 | $4,8-6,9$ |

The same procedure applied to the $R b 4$ averages of the latest 9 cycles yields the following results,

Fig. 2. Strong and weak 11-year sunspot cycles, based on the solar rotation period.
Following both smoothing methods the differences in length of the ascending branches of the sunspot curves have become smaller, whereas the scattering in the final values of these durations when Wolf's method is used, is less than when the binomial method is used.

It is worth while to calculate the average course of the sunspot numbers for each of the two groups of solar cycles now accepted. The results based upon the 27 -day averages have been represented in figure 2 . Since the present investigation included only the end of 1958, a great part of the descending branch of the mean sunspot curve for the strong cycles is only supported by four cycles. In concordance with the results set forth above the average sunspot maximum of the weak cycles has been plotted one year later than that of the strong cycles. In this manner both curves start with their minimum at the same place. Both curves show a striking similarity. Especially the maximum of the strong cycles coincides fairly well with a secondary maximum of the weak cycles, whereas the maximum of the weak cycles arrives at the same moment as a secondary maximum of the strong ones. The behaviour of the curves agrees rather well with the results concerning the secondary peaks arrived at in point 2.4.

I emphasize the steep rise of the ascending branch of the sunspot curve when solar activity is strong without well developed secondary peaks (see 2.4, Table 7).

Now, a remarkable feature is that the maximum mean sunspot number reached in the course of weak cycles, as selected here, does not surpass 90 , since I have shown (1959) that in sunspot numbers an obvious threshold value exists near $R=85$, and that the consequences of this fact are obvious in terrestrial phenomena too. I wish to point here to the following previous conclusions. a. As regards the 2 - to 3 -year period in world weather, five of Berlage's six empirical rules regulating the Southern Oscillation (1957) may be united in one general rule concerning the different influence of solar activity in
the two cases of 11-year sunspot cycles reaching maximum $R$ above or below 85 . Evidently the behaviour of strong and weak cycles differs not only with regard to the quantity of sunspots, but also with regard to the quality of solar activity. It appears that the duration of the Southern Oscillation is shortened to two years during strong solar activity but lengthened to three years during weak solar activity. This effect is steered by the sunspot maximum in such a way, that at its passage the connection with the 11-year period is reestablished by one interval of 3 and 2 years respectively.
$b$. As regards the 7 -year period in world weather, two cycles of half this duration, say two air pressure peaks in 7 years occur during solar cycles with maximum $R$ below 85 , whereas during solar cycles with maximum $R$ above 85 three peaks occur in the same interval.
c. The polar lights remain at a high level of frequency for six years after the sunspot maximum during strong cycles, while during weak cycles there is a polar light maximum for one year only, coinciding with the sunspot maximum (see Table 5 in the Appendix and Fig. 3, compiled from Fritz's Tables (1873).
d. A similar opposition between times of high and low sunspot numbers exists in the halo phenomena in Java (Archenhold, 1930; Visser, 1931).

### 2.3 The remaining minor peaks of Waldmeier's smoothed values

The data $R m$ and $R b 4$ (Table 1) have been plotted in the figures 4-13 (A). Moreover the smoothed monthly amounts of WALDMEIER's table 33 have been represented and their extremes with corrected values for the 3 years mentioned in Table 3.

When the unsmoothed 27,275-day averages are compared with those of the monthly means of Zürich the peaks appear to coincide fairly well. This was to be expected because the rotational period of 27,275 days and the month do not differ much. Comparing, however, both smoothed series we state differences of the same character as those of the notable cases mentioned in Table 2. These differences appear to be systematical.

In many cases the minor peaks of Wolf-Waldmeier's curves are situated just between the secondary peaks of the new curves (see the Figures 4-13 (A)).

This unexpected effect results because Wolf's interval of 13 months is unduely long, and the equal weight given to 11 of them deforms too much the real features. This is how the differences in the maxima of 1870,1893 and 1907 have been caused. The same applies to the minima of $1889,1901,1924$ and 1954: the Zürich minima occur between minima obtained by the $b 4$
method. This deficiency of Wolf's method is well demonstrated in Table 6 (Appendix) for the years 1947-1949 inclusive. The first column contains the Carrington numbers, the second column the year, the third column the averages $R m$ (Table 1). Then follow, on the left side of the table the results of the smoothing method $R b n$ for $n$ from 1 to 12 , on the right side the results of the equalweight smoothing method from $n=2$ up to 12 , and finally Wolf's last step for $n=13$.

There is no sense in extending the $b n$ method as far as $n=12$ (divisor $2^{12}=$ 4096). Yet it has been extended up to this value in order to get results comparable with those of the other method.

Evidently when the method of the binomial coefficients is used, the extremes remain throughout the whole table at the same level, but for some incidental differences of one rotation. Undoubtedly it is sufficient to stop the calculation at $b 4$. By Wolf's method only exceptionally do the extremes maintain the same level (the maximum of rotation number 1256). Sometimes they run backward (the minimum of No. 1263) or forward (the maximum of No. 1266). In by far the most cases a remarkable reversal occurs, e.g.

$$
\begin{array}{ccr}
\text { rotation number } 1266(\max ) \text { reversal between } n=9 \text { and } n=11 \\
1274(\min ) & 9 & 10 \\
1277(\max ) & 7 & 8 \\
1280(\min ) & 8 & 9
\end{array}
$$

1284; the maximum disappears between 8 and 9 .
When the running time interval is too long and equal weight is attached to all parts of the overlapping series the central extreme is driven from its original position by the influence of an opposite extreme at one end of the interval; its sign is reversed by the influence of opposite extremes at both ends of the interval. For instance outstanding reversals appear in the 11 -year cycles No. 14 and 18 (figures 8 and 12). With regard to cycle No. 18 it may be remarked that Waldmeier, in his table 32, distinguished two maxima in sunspot numbers: 151,8 in May, 1947 and 148,5 in October, 1948. The second peak, marked $M_{2} W$ in Figure 12, coincides fairly well with a secondary minimum. The next peak, 136,0 in June 1949, equally concurs with a minimum.

Which of the two smoothing methods is to be preferred depends on the purpose, as described above, but undoubtedly the binomial averages fit the observed data better and reveal a number of particulars which disappear or are distorted by Wolf's method. The consequence of the smoothing method propounded here is that for a number of extremes the epochs given by Zürich require correction.

### 2.4 The secondary peaks of the new sunspot curve

Is there some regularity in the occurrence of the outstanding secondary
peaks? To answer this question the nine 11 -year cycles available have been arranged in order of decreasing maxima, and the number of solar synodic rotations between the peaks, indicated in Table 1 by bold type, compiled in Table 7.

Table 7. Intervals between secondary peaks in the sunspot cycles in synodic rotations

| No. | $\begin{gathered} \text { maximum } \\ R b 4 \end{gathered}$ | before maximum |  |  | after maximum |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 19 | 237,4 | . | . | 12 | 11 |  |  |  |  |
| 18 | 181,2 | . | . | 13 | 11 | 10 | 7 | 23 |  |
| 11 | 163,0 | . | . | 12 | 6 | 7 | 16 | . |  |
| 17 | 138,6 | . | 11 | 7 | 14 | 12 | 16 | 13 | 8 |
| 15 | 136,3 | .. | 10 | 18 | 13 | 11 | . | . |  |
| 13 | 101,0 | -• | 15 | 13 | 12 | 12 | 19 |  |  |
| 12 | 89,4 | 9 | 8 | 17 | 18 |  | $\therefore$ |  |  |
| 16 | 88,4 |  | 15 | 15 | 17 | 6 |  |  |  |
| 14 | 84,2 | 10 | , |  | 9 | 12 | 6 | 10 |  |

Notice that the number of secondary peaks before the maximum decreases from 3 to 1 for increasing $R b 4$. This feature concords with the steep rise of the curve in Fig. 2, mentioned in 2.2.
The intervals show a wide scattering from 6 to 19 synodic rotations and one exceptionally long duration of 23 units. The data given by Table 7, may be summarized as follows.

Average duration of peak intervals in synodic rotations

|  | before the maximum | after the maximum | total mean |
| :--- | :---: | :---: | :---: |
| $\max R b 4>105$ | 11,9 | 11,9 | 11,9 |
| $\max R b 4<105$ | 11,9 | 12,1 | 12,0 |
| total | 11,9 | 12,0 | 12,0 |

The average duration of the intervals is 12 synodic rotations (nearly 11 months), differing distinctly from one year ( 13,5 rotations).

Table 8, exposing the frequencies of the different intervals between peaks in the new sunspot curve ( $f$ and $f b 4$ ), shows some remarkable features.

Intervals of less than one year preponderate considerably. We note 30 intervals of 6 to 13 rotations against 12 intervals of 14 to 23 rotations. Each of the four groups shows the same effect. Moreover the most frequent interval before the maximum is smaller than the one after the maximum ( 9 rotations
against 12), whereas during weak sunspot cycles it is smaller than during strong cycles (12 rotations against 9).

## 3. THE LONG PERIOD OF EIGHT 11-YEAR CYCLES

Table 33 of Waldmeier's treatise [ $E$. und P. p. 153] contains the maxima among the smoothed relative sunspot numbers, $1615,5-1727,5$, calculated by W. Gleissberg by means of backward extrapolation of the "long period". Here is meant the period of seven 11 -year cycles, according to Waldmeier (p. 156-157), after being devised by Wolf in 1862, propagated by K. StumpF [1930] and W. Gleissberg [1941-1951]. Other adherents to the belief in a significant solar period of this duration are H. H. Clayton [1947], H. C. Willett [1951] and D. J. Schove [1955]. Nevertheless, the duration of this long period most probably is 89 years (including eight 11 -year cycles) as was shown by C. Easton [1917] on the ground of his thorough investigation of the course of winter temperatures in Western Europe since A.D. 760. He was able to deduce an uninterrupted series of winter temperatures, starting with the year 1205, and pointed out a close connection between this 89 -year period and the 11 -year sunspot cycle. He showed that this long temperature cycle could be divided into four groups of two solar cycles, each group with its own characteristic features, thus recognizing the fundamentality of the two-cycle interval, long before the reversal of the magnetic polarity of the sunspots at the time of the minimum was detected by G. E. Hale [Waldmeier, E. und P., p. 176-177]. Perhaps the strongest argument for the physical reality of the 89 -year period is its accord with this 22 -year sunspot period. Moreover the present extremely

| 1788,1 | 141,2 |  | 1805,2 | 49,2 |  | 1816,4 | 48,7 |  | 1829,9 | 71,7 |  |
|  |  | 17,1 |  |  | 11,2 |  |  | 13,5 |  |  | 7,3 |
| 1883,9 | 74,6 |  | 1894,1 | 87,9 |  | 1907,0 | 64,2 |  | 1917,6 | 105,4 |  |
|  |  | 10,2 |  |  | 12,9 |  |  | 10,6 |  |  | 10,8 |

strong 11-year cycle is falling strictly into line with Easton's long period, whereas according to Willett's forecast it should have been very weak and very long.

In Table 9 Waldmeier's smoothed data have been arranged in eight columns.

It should be remarked that the sunspot numbers before 1819 are not trustworthy. According to Brunner [1945] the sunspot numbers for the years 1749-1783 are based on an annual average of 90 observations ( 1 in 4 days), for the years $1784-1818$ on an average of 70 ( 1 in 5 days) and for the years 1819-1848 on an average of 260 ( 3 in 4 days). The small number of observations before 1819 does not allow of far-reaching conclusions.

It may be emphasized that great anomalies in the sunspot period (ranging from 7,3 to 17,1 years) occur only in the first row of Table 9 . These discrepancies may have influenced the results. Yet the latest long period, starting in 1867, reveals the same effects.

Table 10 contains the results for this most recent long period, calculated with the $R b 4$ smoothing method (cycle No. 11-18). It contains also the averages of Table 9 , arranged in such a way that they agree with the period 1867-1956; that is they start with cycle No. 5.

Table 10. Easton's period, 1867-1956
Rb4 averages, compared with the results of Table 9

| No. | Max. Rb4 | duration <br> years | No. | Max. $R_{W}$ <br> (Waldmeier) | duration <br> years |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 11 | 163,0 | $\mathbf{1 1 , 9}$ | 5 | 107,9 |  |
| 12 | 89,4 | $\mathbf{1 0 , 9}$ | 6 | 68,6 | $\mathbf{1 2 , 0}$ |
| 13 | 101,0 | $\mathbf{1 0 , 8}$ | 7 | 56,4 | $\mathbf{1 2 , 0}$ |
| 14 | 84,2 | $\mathbf{1 1 , 7}$ | 8 | 88,6 | 9,0 |
| 15 | 136,3 | 10,7 | 1 | 105,9 | 10,4 |
| 16 | 88,4 | 9,8 | 2 | 112,4 | 10,1 |
| 17 | 138,6 | 10,5 | 3 | 121,8 | 9,8 |
| 18 | $\mathbf{1 8 1 , 2}$ | 9,6 | 4 | $\mathbf{1 6 6 , 2}$ | $\mathbf{1 1 , 5}$ |

In both series the 89 -year period is well developed. They show another remarkable feature, the unequal length of the eight 11 -year cycles used. These unequal lengths are arranged systematically, making the ascending branch shorter than the descending one.
ascending branch descending branch
$1750-1958 \quad 9,0+10,4+10,1+9,8=39,3$ y $\quad 11,5+13,6+12,0+12,0=49,1$ y $1867-195610,7+9,8+10,5+9,6=40,6$ y $\quad 11,9+10,9+10,8+11,7-45,3$ y

This feature is strikingly similar to a well-known feature of the 11 -year cycle: a steep rise before the maximum and a slow fall thereafter.

Here again typical differences occur with regard to strong and weak sunspot cycles [VISSER, 1959].

## 4. THE 27-DAY PERIOD

### 4.1 The 27-day period in sunspot numbers

Strips B of the Figures 4-13 contain the solar rotation period in a simplified form. Each slanting line represents one rotation in such a way that the completion of each rotation at the upper end joins the start of the following rotation at the lower end of the next slanting line, the positive deviations (the maxima) have been indicated by heavy lining. Interruptions in the sequences of these slanting lines show where periodicity is lacking. The Carrington numbers have been inscribed at the base line of the part A of the curves, the dates at the top line.

The very many cases and long sequences of recurrence reveal the prominence of the rotation period in sunspot numbers. The maxima in the slanting lines, however, demonstrate also the capricious character of this short sunspot cycle. It starts and ends unexpectedly, the phase is by no means constant. The phase can even change suddenly in long sequences. The maxima run forward or backward repeatedly, betraying the displacement of a disturbed region over the Sun's disc.

### 4.2 The 27-day period in terrestrial phenomena

The strips $C$ of the Figures 4-13 indicate by heavy lining the sequences of the period in the daily maximum temperatures $t$ at De Bilt since 1863, the magnetic character ( $C$ since 1891, and $K$ since 1940) at De Bilt-Witteveen, and the ionospheric index $I$ at De Bilt since 1952. These geophysical series always exhibit sunspot periods, sometimes all the items fluctuate simultaneously.

The strips D expose the running $b 4$ averages of $C, K$ and $I$. An outstanding feature of these curves is their relative independence of the sunspot curves $A$.

As it is the author's intention to devote a future publication to these terrestrial data he may confine reference here to his earlier publications on heat waves occurring in the years 1947 and 1953 [Visser, 1954 and 1958]. The first paper deals with the daily maximum temperatures of 69 stations in Western Europe in 1947. The second paper concerning observations made at 74 stations in the United States in 1947 and 1953, is summarized here.

The research has been based on the pure 27 -day period, introduced by Bartels. The central day of five consecutive days with the highest relative sunspot numbers has been considered the epoch of the maximum. The temperature deviations have been arranged in such succession that each of the sunspot maxima selected coincided with the central day of the row of 27 temperature deviations. Thus the behaviour of the temperature during 13 days before up to 13 days after the sunspot maximum has been studied. The result is accumulative. The influence of each individual sunspot period on the temperature may be
weak, but by repeating the method for consecutive periods in quite the same way, the influence becomes more and more obvious when actually present. For each series of selected recurrences the 27 daily averages both of the sunspot numbers and of the maximum temperatures have been calculated and the results harmonically analysed, the analysis being limited to the first harmonic.

Fig. 14. Maximum day and reduced amplitude, 1947; sunspots, storms in the $F 2$ layer, daily maximum temperatures in Europe and the United States.

To check the reliability of the harmonics found for each of the 27 values obtained, the difference "observed minus harmonic" has been determined, and the standard deviation $\sigma$ of this series calculated. It is required that $\sigma$ be small, or better that $a / \sigma$ be large. The latter ratio is defined as the reduced amplitude $a_{r}$. For the sunspot numbers it amounted to 4 or more, for the temperatures it reached values of 1,5 and more. For $a_{r}>1$ the concordance may be consider-
ed to be sufficient. Yet, $a_{r}=0,8$ has been taken as the lowest amplitude acceptable ${ }^{1}$.

A division of the United States into six areas was made; East Coast, East and Center (in the East); transition zone East-West, West and West Coast (in the West). It was not always possible to fix the limits between these areas exactly

Fig. 15. Maximum day and reduced amplitude, 1953; sunspots, storms in the $F 2$ layer, ionospheric index, daily maximum temperatures in Europe and the United States.
and so I have preferred the periodic character above the geographical position. Thus, for example, Akron, Ohio and Elkins, West Virginia, are among the East Coast stations, though they are over 200 miles inland.

[^0]The complete results of the investigation are represented in the clock diagrams, Figure 14 for 1947 and Figure 15 for 1953. The 27 days of the period have been arranged as the figures of a clock-face and the stations have been plotted by means of the maximum day and the reduced amplitude as polar coordinates.

The lower limit of $a_{r}=0,8$ has been indicated. In these figures some other phenomena have been introduced which will be discussed later.

As a consequence of the method used the sunspot maximum occurs at Day 13,5 ; its reduced amplitude lies far outside the limits of the figures.

In Fig. 14, starting with the maximum sunspot day 13,5, we find a maximum of magnetic storms in the $F 2$ layer of the ionosphere at Day 16-17. The $F 2$ data refer to Slough, England (S) and Washington D.C. (W). They represent the daily number of storm hours, harmonically analysed in the same way as those of the other observations. Both stations agree very well and, obviously, the 27-day period is well established in the magnetic storms of the $F 2$ layer.

Some days later temperature maxima in Europe occur (Day 20-21). The three stations plotted in the diagram are Den Helder (DH) and De Bilt (DB) in the Netherlands and Marburg in Germany (M). The results closely agree with those earlier deduced for Western Europe [Visser, 1954]. As to the stations in the western United States the results may be interpreted as follows. The temperature minimum must occur with a time interval of a half period after the temperature maximum. This means that the minimum must present itself at Day 22-23, two days later than the European maximum. It may be concluded that in Europe and the western United States the phases of the temperature wave are opposite. At about the same epoch the eastern United States have their maximum, though poorly developed.

In Fig. 15 the western and eastern areas of the United States are shown to behave in 1953 in quite the same way as in 1947. However, effects in the $F 2$ layer and in Europe are contrary to those noted in 1947. The $F 2$ storms experience their maximum at Day 4 and, therefore, their minimum at Day 18 . The two $F 2$ points in the diagram represent the daily amount of storm hours at Washington (as in 1947) and the $I$-index in De Bilt. Again there is a good agreement and the period is well developed in the ionosphere. In 1953 as in 1947 European temperature maxima follow the $F 2$ storm maxima (Den Helder and De Bilt, as before, and Kassel-Harleshausen, K, in Germany) at Day 5. Their minimum occurs at Day 19. The results are combined in Table 11.

In Table 12 are summarized the final results of the harmonic analysis of the sunspot numbers, and of the daily maximum temperatures at two stations in the Netherlands (Den Helder and De Bilt for 1947 and 1953) and at two stations in Germany (Marburg for 1947 and Kassel-Harleshausen for 1953), as well as of the harmonic analysis of the daily numbers of $F 2$ storm hours at Slough and Washington, and of the ionosphere index at De Bilt.

$a=$ harmonic amplitude; $\varphi=$ phase angle; $D=$ maximum day; $\sigma=$ standard deviation; $a_{r}=$ reduced amplitude.

### 4.3 The sunspot areas

The Greenwich Observatory publishes, since 1874, the photoheliographic observations of sunspot areas. In order to compare the daily results of these measurements with the daily relative sunspot numbers, I have tested a number of cases, making use of the daily amounts of whole spot projected areas.

As to this point Waldmeier [E. und P. p. 140] states:
Die Beziehung zwischen Relativzahl und Fläche für einen einzelnen Tag ist ziemlich locker; dagegen zeigt sich schon in den Monatsmitteln ein sehr enger Zusammenhang zwischen diesen beiden Masszahlen. Im Mittel besteht zwischen der Greenwicher Fläche $F$ und der Zürcher Relativzahl $R$ die Beziehung:

$$
F=16,7 R
$$

Dabei ist $F$ inbezug auf perspektivische Verkürzung korrigiert und in Millionsteln der Sonnenhalbkugel ausgedrückt. Die Bestimmung von $F$ erfordert einen längeren Arbeitsgang und setzt gute photographische Sonnenaufnahmen voraus, während $R$ auch mit sehr einfachen Mitteln bestimmt werden kann und sofort zur Verfügung steht. Bei $R$ geben neben der Gruppenzahl die kleinen Flecken den Ausschlag, bei $F$ die grossen; da aber gegen den Sonnenrand hin die kleinen mehr und mehr verschwinden, kommt bei $R$ den Flecken der Zentral-
zone automatisch ein grösseres Gewicht zu als den randnahen, was wohl der Grund dafür ist, dass sich $R$ bei der statistischen Untersuchung solarterrestrischer Zusammenhänge besser bewährt hat als $F$.
When considering the terrestrial influence of sunspots, beyond doubt greater importance should be attached to the spots in the Sun's central zone than to those near the Sun's rim. Hence the projected areas (the areas as "measured in the photograph") should be preferred above the corrected areas chosen by Waldmeier. A control of both the projected areas and the corrected areas for 12 solar rotations in 1947 and 12 solar rotations in 1953, revealed that the reduced amplitude was larger for the corrected areas in 1947, but smaller in 1953 (compare Table 14). These results, however, were not sufficient to induce me to quit the projected areas.

The general average of the $A$ proj/ $R$ ratio, through 13827 -day periods involving 3726 days, amounts to

$$
A \operatorname{proj} / R=21,8
$$

The scattering is rather large, as shown in Table 13.
Table 13. The scattering in the $A$ proj $/ R$ ratio

| $R$ | $n$ | $R m$ | $A m$ | $A$ proj $/ R$ | extremes |
| :---: | :---: | ---: | :---: | :---: | :---: |
| $1-10$ | 23 | 6,7 | 88,6 | 13,2 | 1,0 and 47,4 |
| $11-20$ | 22 | 14,4 | 214,8 | 14,9 | 5,0 and 37,2 |
| $21-40$ | 26 | 27,6 | 582,4 | 21,6 | 9,8 and 39,2 |
| $41-80$ | 24 | 61,8 | 1076,4 | 17,4 | 13,1 and 28,2 |
| $81-120$ | 22 | 100,4 | 2261,5 | 22,6 | 13,8 and 33,5 |
| $121-209$ | 21 | 148,6 | 3670,0 | 24,7 | 16,1 and 40,0 |
| general mean |  | 59,9 | 1349,7 | 21,8 |  |

The results suggest an increase of the $A \operatorname{proj} / R$ ratio with increasing sunspot numbers. This feature may be due to $R$ being underestimated or $A$ being overestimated. I favour the first supposition, which would betray a certain insufficiency of Wolf's method of counting $R$ at high solar activity. The corrected areas (1947 and 1953) show the same effect, viz.

|  | $R$ | $n$ | $R m$ | $A$ corr | $A$ corr $/ R$ | extremes |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1953 | $1-25$ | 12 | 13,7 | 141,2 | 10,3 | 1,0 and 19,6 |
| 1947 | $121-209$ | 12 | 156,7 | 2707,4 | 17,4 | 12,0 and 30,0 |

### 4.4 Harmonic analyses

Table 14 (Appendix) contains the results of the harmonic analysis of 91 27 -day waves in 15 groups.

It is impossible to analyse harmonically a wave through a broken number of days (i.c. 27,275 ), since the observations refer to full days. The best approximation of this time interval is 27 days. The discrepancies in the phase angle do not matter when different observations during the same time interval are compared, because they influence all results in the same way. Another solution of the difficulty is using time intervals of no more than 4 or 5 solar rotations, for in this case the differences may be neglected. This method is useful when seasonal effects are surmised, for then the number of rotations can be restricted to one season.

Contrary to the method earlier applied for the U.S. temperatures [VISSER, 1958] the data have now been inscribed in chronological order in 27 rows. Therefore the accumulative effect is lost (see point 4.2), but the advantage is that now the true location of the sunspot maximum on the Sun's disc is found.

The phenomena analysed are, $R$, the relative sunspot number; $A$, the projected area; $A c$, the corrected area; Fac, faculae projected area; $t$, the maximum temperature De Bilt; $C$ and $K$, the magnetic character figures De Bilt-Witteveen; $F 2$, the number of ionospheric storm hours Washington; $I$, the ionospheric index De Bilt; $P$, the air pressure Jakarta.

The results of the harmonic analysis are, $m$, the average value; $a$, the amplitude; $\varphi$, the phase angle; $D$, the maximum day; $\sigma$, the standard deviation; $a_{r}$, the reduced amplitude.

When these results are compared with those arrived at in my paper on the U.S. temperatures (1958) the following displacements of the maximum day may be stated.

> Maximum day now displacement

| $1947 \quad R$ |  |  |  |
| :--- | ---: | :---: | :---: |
| F2 storms Washington | 13,3 | 15,1 | $+1,8$ day |
| Temperature De Bilt | 16,2 | 19,0 | 2,8 |
| $\quad$ mean displacement | 20,8 | 22,3 | 1,5 |
| $1953 \quad R$ |  |  | $+2,1$ |
| F2 storms Washington | 13,6 | 23,2 | $+9,6$ day |
| Temperature De Bilt | 4,4 | 13,2 | 8,7 |
| $\quad$ mean displacement | 5,5 | 13,4 | 7,9 |
|  |  |  | $+8,7$ day |

The displacement of the sunspot maximum day is due to the fact that this maximum day has been fixed originally on day 13,5 but now is set at its true location on the Sun's disc. The terrestrial phenomena follow exactly the same course. It means that the dials of the clocks in the Figures 14 and 15 must be put forward over 2,1 and 8,7 days respectively, in order to give the true locations.

As a rule the maximum days and the reduced amplitudes of $R$ and $A$ (projected area) behave similarly: the average maximum day is 13,1 in both cases,
the reduced amplitudes are 3,6 and 3,7 respectively. Also the corrected area falls into line (1947 and 1953). However, the maximum faculae projected area lags far behind; obviously its connection with the rotation period is very loose.

For each of the 15 groups the $A / R$ ratio has been calculated. These values behave in the same way as the general means shown above. It might have been

FIG. 16. The opposite character of strong and weak sunspot cycles for $R$ max. day $=13,5$.
expected that the same ratio existed for the amplitudes $a$. This, however, does not appear to be the case. Generally the latter ratio is greater, sometimes considerably greater. It may give an indication that harmonic analysis also yields better results for the sunspot areas than for the relative sunspot numbers.

In cases when both $C$ and $K$ are available, both the maximum days and the reduced amplitudes are in good concordance, except during the year 1953, and even then the maximum days coincide.

The $F 2$-storm hours and the ionospheric index, when available, are in reasonable agreement with the geomagnetic character figures.

The year 1916 has shown a remarkable development of the solar rotation period, following exactly the duration of 27,275 days through 12 rotations (see Table 16, Appendix). In Table 14 two groups of 4 rotations, $I$ and $I I$, have been distinguished. They show a displacement of the maximum day of $11,4-9,9=1,5$ days. The displacement for one rotation is $27,275-27=$ 0,275 days, hence 5 rotations involve 1,375 days. The concordance is remarkably good. It should be remarked that, though the reduced amplitude of the sunspot numbers is smaller for group $I$ than for group $I I$, the reduced amplitudes of the temperature variations at De Bilt and of the air pressure variations at Jakarta behave oppositely.

With reference to the opposite location in clock diagrams of the maxima of the ionospheric disturbances and the European temperatures (Fig. 14 and 15) I have arranged in Table 17 the locations of the different maximum days reduced to $R$ max. day $=13,5$ in decreasing order of $R$. It means that now the dial of the clock has been put back to $R=13,5$. Therefore Figure 16, showing these data as plotted in a clock diagram is wholly comparable with the Figures 14 and 15. The strong cycles, $R=155,6$ and $R=130,0$ have been represented by black circles, the weak ones by open circles. The opposite location is obvious for the weak cycles, $R=9,5, R=12,0$ and $R=14,5$. It should be conceded that the result is not very convincing. The number of cases, however, is small, the scattering rather large. This matter will be dealt with more fully in a following publication.

Table 17. The opposite character of strong and weak cycles.
Maximum days for $R$ max. day $=13,5$.

| Year | Max. $R$ | $F 2$ | $I$ | $C$ | $K$ | $t$ |

## 5. THE 27-DAY PERIOD IN THE ZWANENBURG TEMPERATURES

A good deal of Buys Ballot's investigation, mentioned in 1.1 has been based on the temperature observations at Zwanenburg, midway between Amsterdam and Haarlem, 1729-1861, a series of data of invaluable importance. It was considered to be worth while to apply the insights arrived at in this paper to these old observations. To this purpose the data from the years 1743-1793 inclusive have been analysed in the same way as those of the years 1863-1958. It is not necessary to investigate all Zwanenburg temperatures; the interval of 51 years suffices to test solar influences.

No daily temperature maxima are available. Therefore harmonic analysis has been applied to the highest daily temperature given. The enumeration started on January 16, 1735. This date was chosen so that Rotation No. 1314 coincides with Rotation No. 1 according to Bartels. The rotations in the years considered run from No. 109 (1743, January 10) to No. 798 (1793, December 16).

The results show exactly the same features as those obtained in recent years: 27 -day recurrences in the temperature are numerous and as capricious as they are nowadays.

The daily sunspot numbers obtained in the years considered are too scanty to have any analytical value. We may even venture to state that the temperatures teach us more of the number of sunspots occurring in these times than the sunspot observations do themselves.

Table 15 (Appendix) contains the harmonic constants of 14 obvious recurrences through intervals varying from 4 to 6 rotations (totalling 68 rotations), which is only a small part of those available during the 51 years investigated. The temperature constants, $m, a$ and $a_{r}$, have been expressed in centigrade degrees.

The three series of 1777 and 1778 have been studied before (VISSER, 1954). Then the periods were detected by simply noting the recurrence of maximum temperatures with intervals of about 27 days. Now, by applying a more severe statistical test, the earlier results are confirmed, for instance my statement (loc. cit. p. 378) that only a weak correlation between temperatures and sunspot numbers existed in the second series of 1778 , in which the maxima occurred at about the place of the minima in the first series. The reduced amplitude of the second series attains a value of only 0,6 , which is below the permitted limit of 0,8 , and the time difference of the maxima appears to be 9,4 days.

The results are quite similar to those obtained in recent years. The general averages are as follows,

|  | $n$ | $a$ | $\sigma$ |
| :---: | :---: | :---: | :---: |
| $1753-1792$ | 13 | 1,7 | 1,0 |
| $1863-1958$ | 7 | 1,5 | 1,0 |

One conclusion appears unavoidable. The period of temperature fluctuations given by Buys Ballot (compare 1.1) is a mere result of the erroneous method of analysis which he applied, this method being based on the assumption of an uninterrupted recurrence of the period during the whole interval of 155 years surveyed.

## 6. SUMMARY

The aim of the present paper is to analyse the sunspot cycles of about 11 years and of about 27 days and to deduce some of their features in ways which improve in certain respects on analyses made at the Zürich Astronomical Observatory.
1.3 The new analysis is concerned with data running from January, 1863, up to the end of 1958. Running 27-day averages have been calculated following Bartels's enumeration of solar rotations. Reductions have been applied in order to let these averages fit in with the rotation period of 27,275 days.
1.4 The author started with the smoothing method $\left(R_{1}+2 R_{2}+R_{3}\right): 2^{2}$, applying this same method to the results arrived at and so on, up to 5 original data. The final averages have been called "binomial averages of the fourth power".
1.5 Table 1 (Appendix) and the figures 4-13(A) contain the solar rotational averages $R m$ and the smoothed averages $R b 4$ following the method explained in 1.4.
2.1 Table 2 contains the epochs of the smoothed sunspot maxima and minima, Table 3 some notable differences in Waldmeier's two tables of these epochs.
2.2 A division of the data into only two groups, strong and weak cycles, much better reveals a characteristic level of solar activity ( $R \mathrm{~m}$ between 85 and 90) (Fig. 2), compared with Waldmeier's three groups of strong, moderate and weak cycles. This result wholly agrees with the features of a number of geophysical phenomena, the Southern Oscillation, the 7 -year period in world weather, the polar lights and the halo phenomena in Java.
2.3 In many cases the minor peaks of WALDMEIER's sunspot curves are situated just between the secondary peaks of the new curves. Wolf's smoothing method is evidently based on unduely long intervals whereas the equal weights given to the data deforms too much the real features (Table 6 , Appendix).
2.4 The average duration of the secondary waves in solar activity is equal to 12 synodic solar rotations, but intervals of less than one year preponderate considerably (Table 7). Table 8 demonstrates some features of the frequency of the duration.
3. A long cycle including seven 11-year cycles apparently does not exist. The true duration of a long cycle is obviously eight 11 -year cycles, as stated in 1917 by Easton. A period of this length is clearly present (Table 9).

Its ascending branch is shorter than its descending branch. This feature is strikingly similar to a well known feature of the 11-year cycle.
4.1; 4.2 The figures 4-13 (strips $B-D$ ) show for each 11-year cycle the course of different geophysical phenomena at De Bilt, the daily maximum temperatures, the geomagnetic figures $C$ and $K$, the ionospheric index $I$. The figures 14 and 15 include some phenomena as observed in Europe and the United States.
4.3 The projected sunspot areas of Greenwich Observatory appear to reveal the influence of sunspots on geophysical phenomena better than the corrected areas according to Waldmeier. The scattering in the $A$ proj/ $R$ ratio suggests that the relative sunspot number undervalues solar activity, if this is high (Table 13).
4.4 The results of harmonic analysis of 91 27-day periods, 1916-1953, have been presented in Table 14 (Appendix). The phenomena analysed are: $R$, relative sunspot number; $A$, projected area; $A c$, corrected area; Fac, faculae projected area; $t$, maximum temperature De Bilt; $C$ and $K$, geomagnetic character figures De Bilt-Witteveen; F2, number of storm hours Washington; $I$, ionospheric index De Bilt; $P$, pressure Jakarta.

For each of the 15 groups the $A / R$ ratio has been calculated. As a result of the harmonic analysis the ratio of the harmonic amplitudes $a A$ and $a R$ appears to be generally greater, sometimes considerably greater than the $A / R$ ratio. It may indicate that also the harmonic analysis yields better results for the sunspot areas than for the relative sunspot numbers.

The geomagnetic character figures, the $F 2$ storms and the ionospheric index, when available, are in good agreement.

The opposite location in the clock diagrams of ionospheric data and European temperatures, published earlier (Fig. 14 and 15), is again shown in the results now arrived at, however, not very convincingly (Fig. 16).
5. The Zwanenburg temperatures in the 18th century show exactly the same features as those of recent years. Table 15 (Appendix) contains the harmonic constants of 14 selected series of 27 -day waves in these temperatures, involving 68 rotations.

[^0]:    1 As W. VAN DER BIJL pointed out to me, the experimental limit $a_{r}=0,8$ (that is $a_{r}>0,75$ ) fits the statistical $5 \%$ limit, derived from formula (30.82), Kendall II, p. 434.

[^1]:    * insufficient $(<0,7)$

[^2]:    Bold types: positive deviations

    * Beginning of the Carrington rotations 835-846.
