### Special Section:

The COVID-19 Pandemic: Linking Health, Society and Environment

### Key Points:

- NO<sub>x</sub> emissions derived from TROPOMI observations show reductions for individual Chinese cities of about 35% due to the COVID-19 lockdown
- Emissions of coal power plants and maritime transport show strong reductions (25–40%) during the lockdown
- Urban emissions rebound in March to levels before the lockdown, while emissions of power plants and maritime transport take longer to recover

**Abstract** During the COVID-19 lockdown (24 January–20 March) in China low air pollution levels were reported in the media as a consequence of reduced economic and social activities. Quantification of the pollution reduction is not straightforward due to effects of transport, meteorology, and chemistry. We have analyzed the NO<sub>x</sub> emission reductions calculated with an inverse algorithm applied to daily NO<sub>2</sub> observations from TROPOMI onboard the Copernicus Sentinel-5P satellite. This method allows the quantification of emission reductions per city and the analysis of emissions of maritime transport and of the energy sector separately. The reductions we found are 20–50% for cities, about 40% for power plants, and 15–40% for maritime transport depending on the region. The reduction in both emissions and concentrations shows a similar timeline consisting of a sharp reduction (34–50%) around the Spring festival and a slow recovery from mid-February to mid-March.

**Plain Language Summary** During the COVID-19 lockdown in China, air quality had strongly improved. Here we study what sources were reduced and how much the reduction per city was. We used TROPOMI observations of the Sentinel-5P satellite, which monitors the Earth's atmosphere daily. We focused on observations of the pollutant “nitrogen dioxide,” an important precursor of air pollution in the atmosphere. With our novel methodology we are able to calculate the pollution back to the sources of the emissions, whether these are big cities, industrial regions, power plants, or busy shipping lanes. We applied this method to East China, where the 36 biggest Chinese cities are located. Almost all those cities showed strong emission reductions of 20–50% during the lockdown in February 2020. Besides urban China, we found an average emission reduction of 40% over coal power plants and a reduction in maritime transport by 15–40% depending on the region. The period of reduced emissions lasted until around the end of February, and the emissions slowly returned to normal during the month March 2020. Exception is the region Wuhan, the center of the COVID-19 crisis, where emissions started to rebound since 8 April, the end of their lockdown period.

## 1. Introduction

The year 2020 is an unprecedented year, with the novel coronavirus, causing the COVID-19 disease spreading over the whole world, infecting millions of people and causing hundreds of thousands of fatalities (WHO, 2020). On 11 March 2020, the World Health Organization (WHO) qualified the spread of COVID-19 as a pandemic. To prevent the spread of the disease, many affected countries implemented COVID-19 regulations. China, the first country facing the outbreak of COVID-19, enacted a lockdown from 24 January to 20 March 2020 in the Hubei province where the first cases were reported from its capital Wuhan, while other provinces limited all outdoor activities since the Chinese New Year and gradually resumed the work after 10 February (Tian et al., 2020; Wang et al., 2020).

The strict COVID-19 regulations lead to a reduction of road and air traffic, a temporary closing of companies, and a decrease of industrial productivity. These in consequence affect emissions of air pollutants, especially from the transport and industry sectors, which are significant sources of NO<sub>x</sub> (NO<sub>x</sub> = NO<sub>2</sub> + NO) in cities. Several studies presented a large decrease of NO<sub>2</sub> concentration during the lockdown period in China from both in situ and satellite observations (Huang et al., 2020; Wang et al., 2020). Tropospheric NO<sub>2</sub> column concentrations observed by the TROPOMI (TROPOspheric Monitoring Instrument) on the Sentinel-5P satellite

**Figure 1.** TROPOMI NO<sub>2</sub> columns over East China after the Chinese New Year in 2019 (a) and 2020 (b). NO<sub>x</sub> emissions for the same period in 2019 (c) and 2020 (d) derived with DECSO.

decrease about 35% over China and some areas up to 60% during the COVID-19 regulation period compared to the same period of 2019 (Bauwens et al., 2020; Liu et al., 2020; Zhang et al., 2020). In March 2020, after the resumption of work and the gradual lifting of the lockdown restrictions, the NO<sub>2</sub> concentrations quickly increased to similar levels as in the previous year (Bauwens et al., 2020). Because NO<sub>2</sub> concentrations are

affected by meteorology, chemistry, and transport, large concentration variations are expected from day to day. Therefore, the concentrations alone provide only an indication of the impact of the COVID-19 measures on air pollution. Bottom-up inventories are usually updated with few years delay due to the complexity of gathering all statistic information on source sector, land-use, and sector-specific emission factors. A top-down approach using satellite observations has been demonstrated to be able to accurately and quickly provide emission estimates (Miyazaki et al., 2020; Stavrou et al., 2013). Here we derived the  $\text{NO}_x$  emissions by using the satellite observations and a chemistry-transport model (CTM). The model is driven by meteorological analyses, accounting for the weather-related variability. The high spatial resolution of the TROPOMI observations and the inverse modeling system allows us to quantify the impact of the COVID-19 measures and distinguish emissions from cities, power plants, and maritime transport separately. Recently,  $\text{NO}_x$  emissions derived from the high resolution  $\text{NO}_2$  observations of TROPOMI have been reported by Goldberg et al. (2019) and van der A et al. (2020).

To this purpose, we use the Daily Emission estimates Constrained by Satellite Observations (DECISO) algorithm, which has been demonstrated to capture emission changes in a short time period at city level (Ding et al., 2015; Mijling & van der A, 2012). This study presents  $\text{NO}_x$  emissions estimated from Sentinel-5P TROPOMI observations from 2019 to April 2020 over East Asia. The high spatial resolution satellite observations and daily global coverage allow us to monitor fast emission changes per city due to the implementation and to the relaxing of COVID-19 regulations.

## 2. Methodology

### 2.1. $\text{NO}_2$ Observations by TROPOMI

The Copernicus Sentinel-5P satellite carries the TROPOMI instrument (Veefkind et al., 2012). TROPOMI is a spectrometer combining a high spectral resolution with high spatial resolution ( $3.5 \times 5.5 \text{ km}^2$  at nadir for the  $\text{NO}_2$  observations), low noise, and a daily global coverage. Despite the much smaller footprints, the spectral fits of the individual TROPOMI ground pixels have 30% smaller noise than those from the earlier Ozone Monitoring Instrument (OMI), and the average values agree well within 5% (van Geffen et al., 2020).

Validation studies (Judd et al., 2020; Tack et al., 2020; Verhoelst et al., 2020) show that the currently available TROPOMI product (versions 1.2.2 and 1.3.0) has tropospheric columns with effectively a typical systematic bias of about  $-15\%$  (see Supporting Information), and we expect the derived emissions from these observations to be low by such an amount on average. In the relative comparisons discussed in this paper for both columns and emissions we expect a large part of such a multiplicative bias to cancel out.

Figures 1a and 1b show the mean TROPOMI  $\text{NO}_2$  tropospheric column observations gridded on a  $0.02^\circ$  by  $0.02^\circ$  grid for the periods 8–28 February 2020 compared with 18 February–4 March 2019, both after the Chinese New Year holidays. Very prominent concentration reductions are observed in 2020 compared to 2019.

The TROPOMI tropospheric  $\text{NO}_2$  columns are pre-processed into “super-observations,” representing the integrated average of the TROPOMI observations over the  $0.25^\circ \times 0.25^\circ$  grid cells of the model after filtering for clouds. The basic concept of super-observations has been explained in Miyazaki et al. (2012) and Boersma et al. (2016). They have shown that clustering individual observations into super-observations has a positive impact on the analysis. The super-observation error takes into account spatial correlations between individual TROPOMI observations as well as representativity errors in the case of incomplete coverage. Averaging kernels are also computed for these super-observations and are used in the emission estimates described below. This has the advantage that the inversion result becomes independent of the coarser-resolution of the a priori profile used in the retrieval of the tropospheric column.

### 2.2. $\text{NO}_x$ Emissions From DECISO

DECISO is a state-of-the-art inverse algorithm developed by Mijling and van der A (2012) to update daily emissions of short-lived atmospheric constituents using an extended Kalman filter in which emissions are translated to concentrations via a CTM and compared to the satellite observations. The sensitivity of concentrations to emissions is calculated from a trajectory analysis to account for transport of the short-lived gas by using a single CTM forward run. DECISO has been successfully applied to  $\text{NO}_2$  observations from OMI and

TROPOMI over different regions (Ding et al., 2017, 2018; Mijling & van der A, 2012; van der A et al., 2020). In this study, daily  $\text{NO}_x$  emissions from January 2019 to April 2020 over East Asia (102–120°E, 18–50°N) are derived with DECSO using the Eulerian regional off-line CTM CHIMERE v2013 (Menut et al., 2013) and TROPOMI  $\text{NO}_2$  observations. The implementation of CHIMERE v2013 in DECSO is described in Ding et al. (2015). The latest development and validation of DECSO are presented in previous studies (Ding et al., 2017; van der A et al., 2020). In our current approach, we apply DECSO to the super-observations of TROPOMI instead of directly using individual TROPOMI observations. Figures 1c and 1d show the mean  $\text{NO}_x$  emissions derived from TROPOMI for the same period as Figures 1a and 1b in 2019 and 2020 after the Chinese New Year. We see lower  $\text{NO}_x$  emissions in February 2020.

### 2.3. In Situ Observations

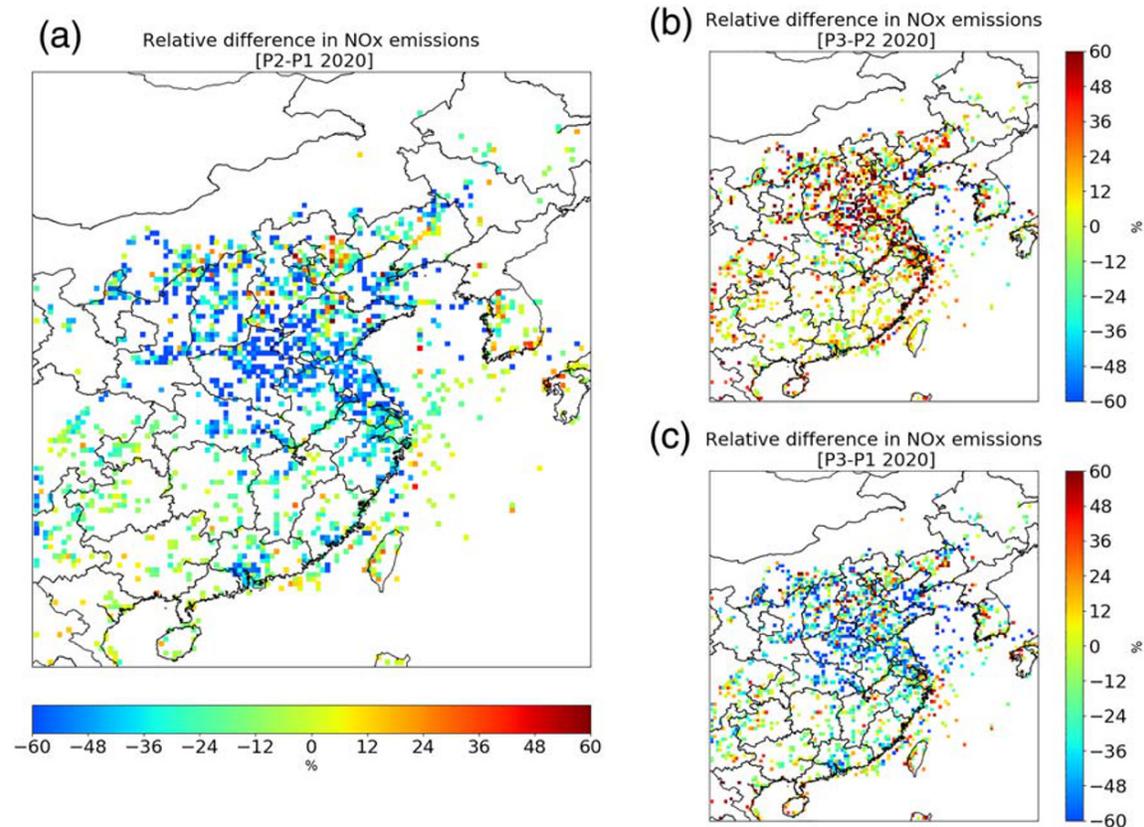

More than 1,500 in situ stations covering all major cities in China are operated by the China National Environmental Monitoring Center. They provide hourly observations of the pollutants  $\text{PM}_{10}$ ,  $\text{PM}_{2.5}$ ,  $\text{O}_3$ ,  $\text{NO}_2$ ,  $\text{SO}_2$ , and CO (Bai et al., 2020).  $\text{NO}_2$  is measured by a chemiluminescence technique (Zhang & Cao, 2015). Data can be accessed via websites of third parties (such as <http://www.pm25.in> and <http://www.aqicn.org>). For this study we have averaged the various in situ  $\text{NO}_2$  observations in a city to a single value per hour for each of 36 selected major cities. For comparison with model results, we calculated a daily value based on the observations from 10:00 to 18:00 local time. The daytime selection is due to large inaccuracies in simulations of the nighttime boundary layer height.

### 2.4. Ensemble Modeling

An operational multi-model forecasting system for air quality has been developed to provide air quality services for urban areas of China (Brasseur et al., 2019; Petersen et al., 2019). This system has been developed within the EU-funded FP-7 projects: MarcoPolo and PANDA. The ensemble model system includes nine global and regional chemistry-transport models from different research institutes from Europe and China. The ensemble service has a typical resolution of about 20 km. It provides daily forecasts of ozone, nitrogen oxides, and particulate matter for the 36 largest urban areas of East China (i.e., population higher than 3 million according to the census of 2010; NBS, 2010). These individual 3-day forecasts as well as the mean and median concentrations are publicly accessible (<http://www.marcopolo-panda.eu>). The emission inventories used as input to the models of the ensemble do not account for the Chinese New Year or the COVID-19 lock down period. Therefore, the ensemble model represents the business-as-usual scenario.

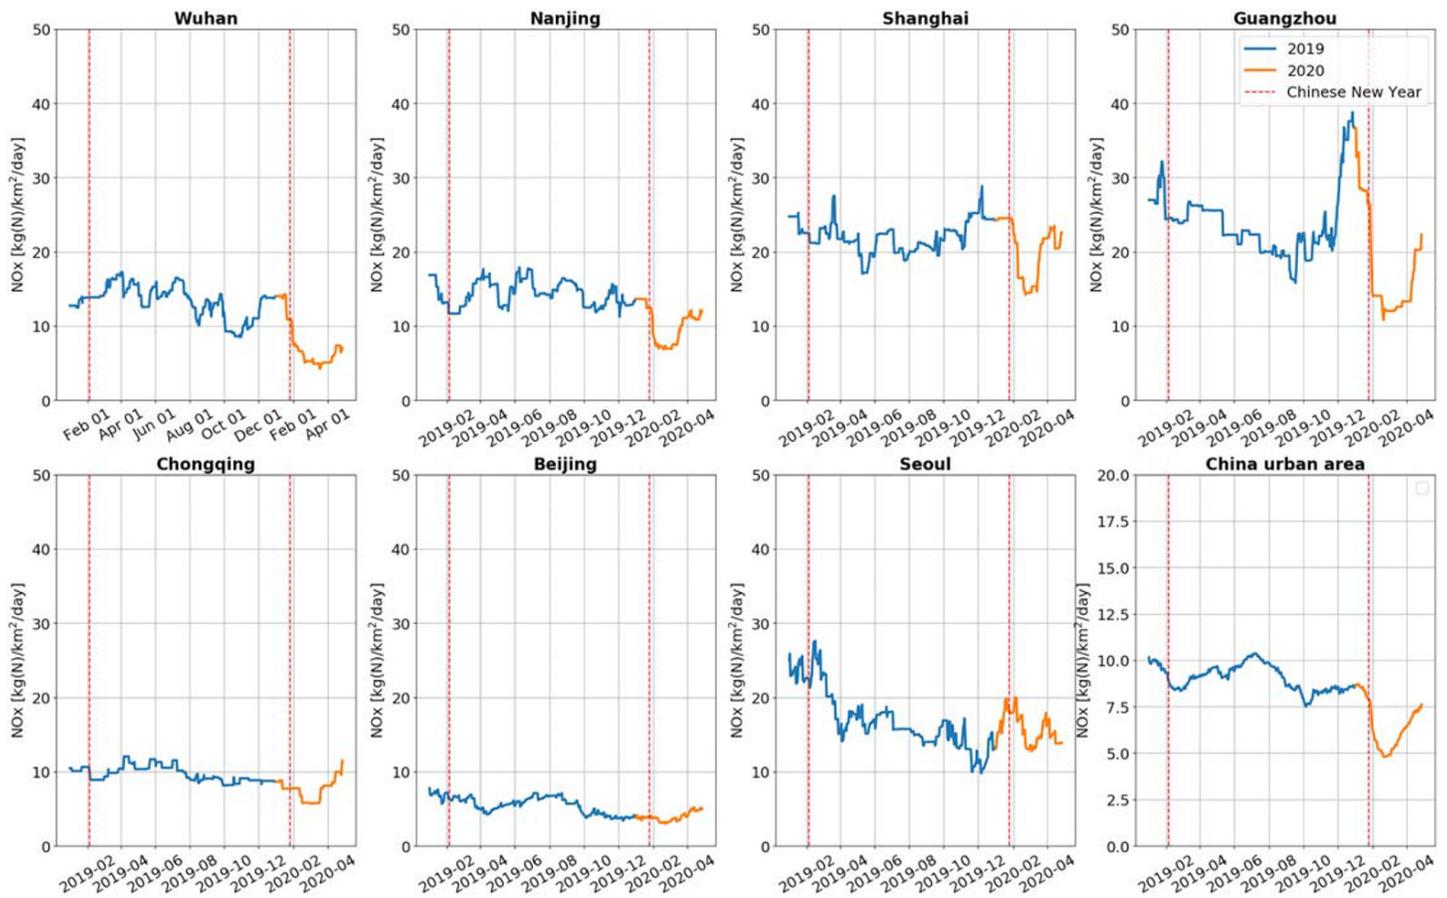

## 3. $\text{NO}_x$ Emissions Reductions

$\text{NO}_x$  emissions have been affected since the strict regulations started in China, especially in Hubei. We select three periods to quantify the impact of the COVID-19 regulations. The first period (P1) is 3 weeks before the implementation of the COVID-19 regulations, 3–23 January in 2020, which is also just before the Chinese New Year. The second period (P2) is 8–28 February, which is regarded as the regulation period. The third period (P3) is from 18 March to 7 April, when most regions in China resumed working. We calculated the average of  $\text{NO}_x$  emissions derived with DECSO in each period and compare their differences. Figure 2 shows the relative changes of  $\text{NO}_x$  emissions during the selected three periods over the grid cells with high anthropogenic (above 3 kg N/km<sup>2</sup>/day)  $\text{NO}_x$  emissions. We observe a strong decrease by at least 30% of  $\text{NO}_x$  emissions over China in P2 compared to P1 (Figure S1 shows the emission changes on provincial level). A few grid cells with increased emissions often coincide with industrial areas. In P3,  $\text{NO}_x$  emissions increased compared to P2 but are still lower than in P1 because of the step-wise resumption of work and social life. The  $\text{NO}_x$  emissions in South Korea are not significantly changed in P2 compared to the changes in China during the three periods (Figure S1), because South Korea adopted less restrictive COVID-19 regulations, mostly on voluntary basis (Bauwens et al., 2020). In Figure 2, we see that the  $\text{NO}_x$  emissions over sea also decrease. We calculate the  $\text{NO}_x$  emissions over the ship lanes over Chinese seas defined in the study of Ding et al. (2018). The emissions due to sea-transport from Shanghai to Guangzhou are less affected than the transport over land and are found to decrease by about 25% in P2 and increase again with 18% in P3 in comparison to P2. A more significant emission decline was found in the Yellow Sea and Bohai area, where  $\text{NO}_x$  emissions reduced by about 41% in P2 and continued decreasing by 6% in P3.

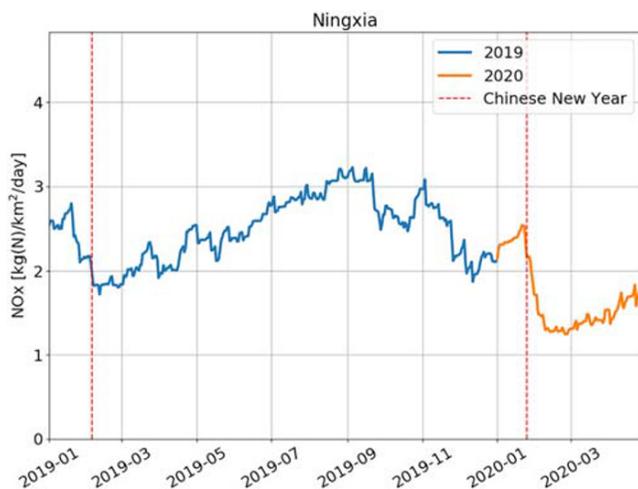

**Figure 2.** The relative difference in NO<sub>x</sub> emissions between (a) P2 and P1, (b) P3 and P2, and (c) P3 and P1. P1 is 3–23 January. P2 is 8–28 February. P3 is 18 March–7 April. The changes in emissions are shown in the figure for emissions higher than 3 kg(N)/km<sup>2</sup>/day in P1 to remove areas with dominating biogenic emissions or rural areas.

At city level changes in NO<sub>x</sub> emissions started from January 2019. Figure 3 shows the time series of emissions at six large cities in China and in Seoul, the capital of South Korea. We infer a very strong NO<sub>x</sub> emission decrease of more than 50% during and after the 2020 Chinese New Year in Wuhan, where the COVID-19 outbreak was first recorded and very strict lockdown regulations were adopted. At the other five Chinese cities, we also observe a much stronger decrease after the Chinese New Year in 2020 than in 2019. In addition, the duration of the period with low emissions is much longer. Most cities in China display a stronger decrease in 2020 (see Table S1), which is attributed to the COVID-19 measures. The averaged NO<sub>x</sub> emission reduction at the selected cities shown in Table S1 is 35%. We also calculate the average reduction of grid cells containing urban areas selected by using the land-use data of the GlobCover Land Cover data set, which was implemented in the CTM by Ding et al. (2015). The inferred emission reduction is about 35% in urban areas, which is the same as the average reduction in the selected cities. Note that the NO<sub>x</sub> emissions are usually lower by about 10% during the Chinese New Year with less business and industrial activities (Ding et al., 2017). The timeline of NO<sub>x</sub> emissions in Beijing shows a slightly different pattern with a relatively low reduction during the COVID-19 lockdown but already strong emission reductions during the politically important “two-sessions” meeting in March 2019, the most important political meeting of China, and especially the celebration of 70th national anniversary of China around 1 October 2019, when many factories were closed and strict emission regulations were enforced (Yang et al., 2020). Figure 3 also shows that the NO<sub>x</sub> emissions start to increase again in March, in line with the step-by-step recovery of the human activities. Except for Wuhan with the emission rebound after 8 April, when the lockdown was lifted, by the end of March all cities reached a level of NO<sub>x</sub> emissions close to what was observed in the same period in 2019. This is consistent with the economic target of China that they will accelerate the return to the precrisis economic level after the temporary economic setback due to the COVID-19 outbreak as was reported by Ouyang (2020).

**Figure 3.** Time series (1 January 2019–28 April 2020) of daily  $\text{NO}_x$  emissions in seven cities and urban China. Six Chinese cities are considered (Wuhan, Nanjing, Shanghai, Guangzhou, Chongqing, and Beijing) as well as Seoul. The location of Chinese cities is shown in Figure S4.

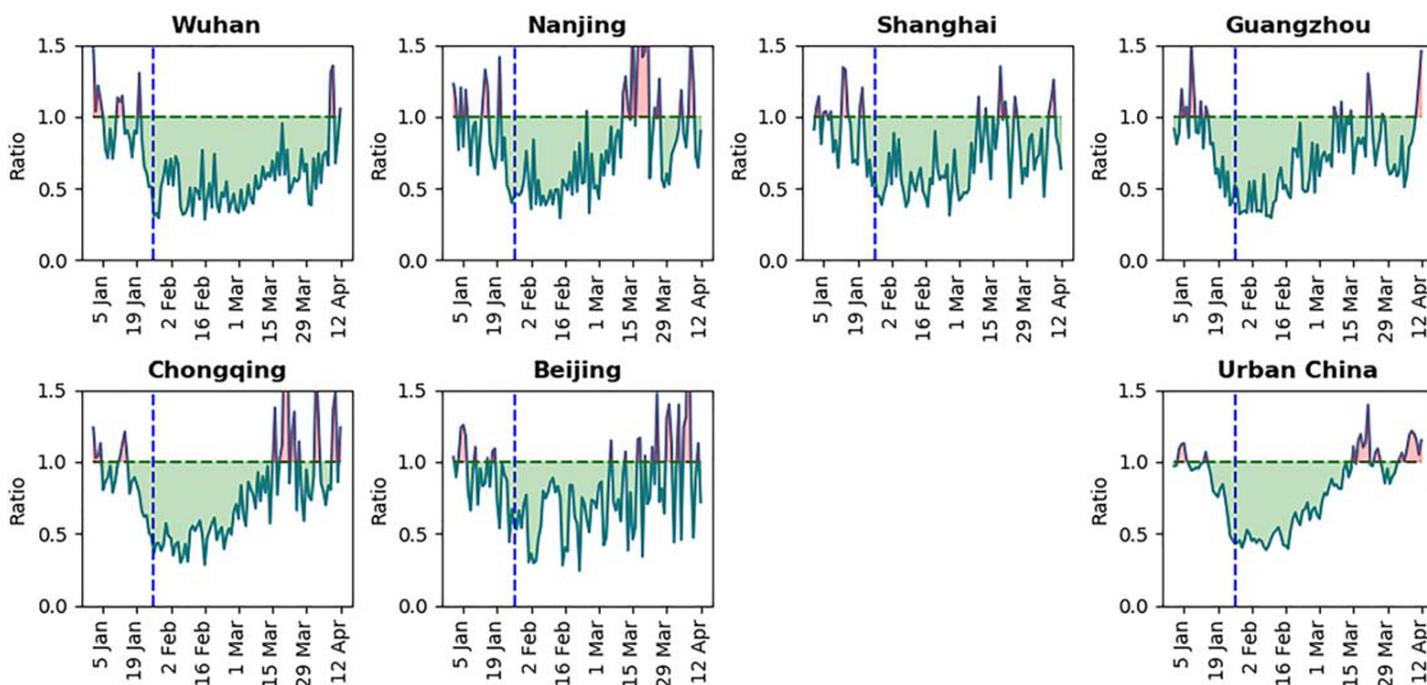

Besides the urban emissions, we find strong reductions of  $\text{NO}_x$  emissions from coal power plants. Figure 4 shows time series of  $\text{NO}_x$  emissions from the Ningxia Province, where the main sources of  $\text{NO}_x$  are fossil fuel power plants (van der A et al., 2017). Ningxia province can serve as an indication of the national energy production by coal power plants. It has a population of about 6 million, only 0.4% of the total population of China. Its coal production and electricity generation from coal power plants are in the top 10 list of provinces, and about 80% of the generated energy is consumed by the industry (Ningxia Statistics Bureau, 2019). Our inversion results indicate that after the 2020 Chinese New Year,  $\text{NO}_x$  emissions dropped about 40% in this province, 20% more than in 2019 New Year period. This shows the impact of the COVID-19 regulations on the energy production, especially in the industrial sector. According to the National Bureau of Statistics of China (2020), the total profit of the first 3 months in 2020 made by industrial enterprises decreased around 40% in China compared to the same period of the previous year. The shrinking of the industrial economy results in lower energy consumption, which is clearly reflected by the decrease of  $\text{NO}_x$  emissions from power plants.

**Figure 4.** Time series (1 January 2019–28 April 2020) of daily  $\text{NO}_x$  emissions in Ningxia Province.

#### 4. Surface Concentration Reductions

The effect of the emission reductions on the surface concentration is very relevant for air pollution. In Figure S2 we show the emissions and the modeled surface concentrations from DECSO based on these emissions.

**Figure 5.** Measured  $\text{NO}_2$  concentrations (from 1 January to 12 April 2020) compared to concentrations of the business-as-usual scenario. Cities are chosen similar to Figure 3, except for Seoul. The Chinese New Year is indicated by the blue dashed line.

Although we see a similar time course in both, the reductions in emissions and surface concentrations are different due to the changing meteorology and lifetime of  $\text{NO}_x$  over time. To further verify the reductions in surface concentrations we used measurements of the in situ stations described in section 2.3. To eliminate the effect of meteorology and transport we compare the measurements of in situ stations with the ensemble model introduced in section 2.4. The model is driven by emission inventories, which are not corrected for the effects of either Spring Festival or the COVID-19 crisis and hence are considered the business-as-usual situation. A possible bias between measurements and model is corrected for by normalizing the results for the first 2 weeks of January. In Figure 5 the ratio between in situ measured  $\text{NO}_2$  and the modeled  $\text{NO}_2$  is shown. The concentration reductions are shown as green area, while increased concentrations are shown in red. The reduction starts around the Chinese New Year and ends in March. Exception is the concentration level of Wuhan that becomes similar to that of the business-as-usual scenario after the first week of April. Table S1 shows the concentration reduction in P2 compared to P1 for the selected 36 cities. The average concentration reduction is 41%, while for emissions the reduction is 35%. A striking difference between Wuhan and the other Chinese cities is the longer duration (by about 1 month) of the concentration reductions.

## 5. Conclusions

To study the impact of the COVID-19 regulations on  $\text{NO}_x$  emissions (one of the key ingredients determining air pollution), we derived daily  $\text{NO}_x$  emissions at a resolution of  $0.25^\circ \times 0.25^\circ$  over East Asia from 2019 to March 2020 by applying the inverse algorithm DECSO to observations from TROPOMI. By grouping the emission into three periods of before, during and after the COVID-19 regulations, we quantified the emission changes on the small spatial scale of city level and from different emission sources such as sea-transport and the energy sector. The observations suggest emission reductions of 20–50% for cities. The emissions reduction of 40% in the Ningxia province reflects the impact of the lockdown measures on the energy sector. Maritime transport is also affected during the COVID-19 regulations, although its emission reductions are dependent on the region. Along the ship track from Shanghai to Guangzhou, the  $\text{NO}_x$  emissions decreased by 25% during the lockdown and increased again by 18% after the work resumption. While in the region of the Yellow sea and Bohai sea, the emissions decrease by 40% and continued decreasing with another 6% also

in March. To further assess the impact of emission reductions, we compared the in situ NO<sub>2</sub> concentration measurements with simulated surface concentrations from models using unaltered emissions. The emission reductions follow a similar timeline as the surface NO<sub>2</sub> concentrations, which show a sharp reduction around the Chinese New Year and a slow recovery from mid-February to mid-March. Wuhan, the city of the epicenter of the COVID-19 crisis, shows large emission reductions in both February and March, reaching nominal levels in April. In general, we found that activities in the cities returned to normal in March, while as an indicator of the economy, emissions of energy production and international maritime transport took a longer time to return to pre-COVID-19 levels (Table S2).

With the NO<sub>x</sub> emissions derived from DECSO using observations from TROPOMI, we are able to get detailed information about the impact on emission changes due to the COVID-19 regulations by accounting for the influence of meteorology, lifetime, and transport of the air pollutants. As the COVID-19 crisis progressively affects all continents, the public health regulations implemented by various countries may have different contributions to air quality. Applying our methodology to different regions can help to quantify the impact of the NO<sub>x</sub> emission reductions by the different regulations on not only the improvement of air quality from urban to local to regional scale.

### Data Availability Statement

This publication contains modified Copernicus Sentinel-5P data 2019–2020. TROPOMI data are available online ([http://www.temis.nl/airpollution/no2col/tropomi\\_data.php](http://www.temis.nl/airpollution/no2col/tropomi_data.php)). We acknowledge the ESA GlobCover project for the land use data set ([http://due.esrin.esa.int/page\\_globcover.php](http://due.esrin.esa.int/page_globcover.php)). The NO<sub>x</sub> emissions data set in this study is available online ([http://www.globemission.eu/region\\_asia/datapage.php?species=NOx\\_TROPOMI](http://www.globemission.eu/region_asia/datapage.php?species=NOx_TROPOMI)).
